

Analysis of intra-annual variability of time series of Sentinel 2 imagery for annual land cover mapping: A case of study in central of Portugal

William A. Martínez B.

1 Problem statement and Motivation

Mapping Land cover land use (LULC) is a fundamental task in any kind of environmental, cultural and political study, since it provides baseline for governments to undertake and monitor policies that look for sustainable livelihoods in harmony with the ecosystems. After almost 4 decades of technological evolution and powerful algorithms in mapping LULC by using earth observation, the research continues looking for adaptation of new and common approaches that can get benefit from big data available through new technology - we never had high spatial resolution images with a temporal resolution of ± 5 days (i.e. Sentinel-2) and with an open data policy.

Generally, the classification methods based the discrimination of land cover types on the spectral differences of the pixel, on the contextual information of the pixel that lead to classify image-objects instead of pixels (Jensen and Lulla, 1987), and on spectral differences of the pixel over the time (Vuolo et al., 2018). However, the last approach has gained especial interest since it makes synergy of the spectral and temporal components. While involving dynamics in the land cover may give insights of long and short land cover transitions (Gómez et al., 2016), this may also contribute to get more consistency in the discrimination of intra classes that are difficult to separate from the static data perspective (Franklin et al., 2015).

The generation of single land cover maps by using time series is a novel approach that has demonstrated superiority over methods based on static data, especially in the discrimination of vegetation where the intra classes variation are slightly similar (Hermosilla et al., 2015). However, its application implies fundamentally an increase in the dimensionality and thus the need both for a dense temporal datasets and for algorithms that can deal with high dimensionality. Classification, viewed from the perspective of time series, may differ from the static data approach in how the similarity between elements is computed. Generally, a time series approach takes advantage of the seasonal response of indices vegetation for different land cover types over the year to compute metrics. For example, Franklin et al. (2015) shows how to reduce dimensionality by calculating metrics of normalized burn ratio. However, these metrics, such as the greatest disturbances year, trend magnitude year, greatest disturbance duration, among others, require the construction of dense temporal dataset for different years that at the same time disregard the rest of the spectral information available. This scenario, raises the curiosity for implementing principal components as technique to reduce dimensionality in the classification and find out possible indexes that describe better the differences among signals of different land cover types.

Besides dimensionality, there are also other factors that complicate the experience of land cover classification using time series. For example, no all agricultural areas for certain crop

type start their sowing and harvesting at the same time (Vuolo et al., 2018), so that, the spectral profiles for the same land cover type can have different phases shift and probably also slight changes in their periods hindering the discrimination of spectral signals over the time. Moreover, when the soil moisture content provided by the rainfall in certain areas is insufficient to support the crop production the irrigation is necessary. In that case, soils with same labels can respond different to the radiance over the year due to distinct irrigation patterns.

Another important aspect that we can highlight, it is how the LULC mapping in terms of algorithms for supervised classification has disregard the capacity of the time dimension since most of the literature cover only random forest as classifier. For example, Vuolo et al. (2018), Franklin et al. (2015) and Hermosilla et al. (2015) show the implementation and good results that random forest classifier (RF) can bring to this problem. RF is part of the most useful and less complex mechanisms available for the classification task; important for its ability to handle high dimensionality and be insensitive to overfitting. However, the emergence of new algorithms and perspectives about how to handle temporal data structures (Bishop, 2006), raises the inquisitiveness for pairing these algorithms in the classification under the times series approach.

To continue advancing in the state of the art of classification using the time series approach alongside imagery of Sentinel 2, is therefore important to know how it is going to be explored the performance of the aforementioned proposals. In this sense, this thesis aims to use images of the Sentinel 2 from January 2017 to December 2017 and COS training dataset developed by DGT (Direção-Geral de Ordenamento do Território, Portugal). Moreover, this thesis, under the new paradigm in remote sensing of the best available pixel (BAP) composites (White et al., 2014), proposes compose images by season. This approach generally benefits classification task in areas with frequent cloudy conditions. However, in this thesis beyond that purpose, it also look for reducing the spatial variation of the crop rotation between an image and another.

2 Objectives

This thesis aims to research three questions:

- Do the integration of a index derived from principal components in time series analysis of sentinel 2 imagery in the classification task lead to a better performance than a study based on static multi-spectral data?
- How do the classification approach based on multi-temporal and multi-spectral data works using random forest and support vector machine classifiers?
- How usable is COS training data in the classification task using multi-temporal and multi-spectral data from sentinel 2 imagery?

Items	September	October	November	December	January	February
Proposal and literature review						
Construct methodology						
Radiometric and atmospheric correction of Images						
Best Available pixel composites by month						
Pipeline to remove noise of training data						
Classifications per image using RF and SVM						
Classifications per composites sing RF and SVM						
Principal component analysis						
Analysis of the performance of a multispectral -multitemporal classification usign RF and SVM						
Conclusions and discussion						
Thesis defense
